Abstract

When a replication fails, scientists have to decide whether to make a second attempt or move on. Psychology researchers who attempt to replicate studies often face this decision, given the empirical rate of replication success in psychology, which is lower than desired. Here, we report 17 re-replications of experiments for which an original replication had failed. In 5/17 of these “rescue” projects (29%), the “rescue” study mostly or fully replicated the original results, albeit with a smaller effect size; in the other 12, the second replication was also judged to have failed. We speculate that successful rescue projects were due to larger sample sizes or methodological changes such as attention checks. In the absence of obvious weaknesses in a failed replication study’s sample or procedure, however, it may be most efficient to stop pursuing an effect after a single failed replication.

1 Introduction

Imagine you are a graduate student, and you run a replication of a study that you are interested in building upon in your research. The replication fails. Perhaps the interaction you hoped for is directionally correct, but the point estimate is small and the confidence interval definitely overlaps 0, with a p -value of .3. Or perhaps the interaction is numerically in the wrong direction and the main effects look different. Whatever the details of the replication failure, you are left with a question: Should you try again and run a re-replication, or should you give up and pick a different study to extend?

In psychology, large scale replication projects have found that around half of studies successfully replicate. Across 100 studies with positive results, the reproducibility project in psychology (RP:P) replicated 36 - 47% depending on the metric for replication success ([Open Science Consortium, 2015](#)). With large multi-site samples, Many Labs 1 replicated 11/13 effects (84.6%), Many Labs 2 replicated 14/28 effects (50%), and Many Labs 3 replicated 3/10 effects (30%) ([Ebersole et al., 2016](#); [Klein et al., 2014](#); [Klein et al., 2018](#)). Camerer et al. (2018) examined 21 behavioral social science studies and successfully replicated 12-14 of them (57%-67%) depending on the metric used. Boyce et al. (2023) reported an average subjective replication score of 49% for 176 replications primary in psychology.

Psychology is not the only discipline where many studies do not replicate. Large scale replication projects in other disciplines have found 39/97 of studies with positive effects (40%) replicating in cancer biology ([Errington et al., 2021](#)), 11/18 studies (61%) replicating in economics ([Camerer et al., 2016](#)), and 31/40 studies (78%) replicating in experimental philosophy ([Cova et al., 2021](#)). Across these disciplines, and

especially in psychology, large-scale replications indicate a substantial chance of scientists encountering failed replications if they try to replicate published findings.

Replications can fail for many reasons, having to do with the original study or the replication. Starting with the original study, one potential reason for replication failure is that the original result is fragile in some way. It could be a statistically unlikely result that was achieved through chance or *p*-hacking, or it could be sensitive to the exact conditions and time it was run under (“hidden moderators”). Another possibility is that the original reported effect size might be inflated due to some combination of heterogeneity, *p*-hacking, low power, and publication bias. A consequence of inflated effect sizes is that replication studies might select a sample size with appropriate statistical power for the reported effect size and then have too small a sample to reliably detect the (true) smaller effect. Replication studies might also end up underpowered due to unexpected attrition or noise in the replication sample.

Other reasons for replication failure are also primarily due to the replication study. A replication could observe different results from the original due to methodological differences. These differences in design could be intentional adaptations, unavoidable changes from lack of access to the original instructions or materials, or changes that were not expected to be critical. A difference in the details of recruitment (e.g., online versus in-person) might mean that particular details of a study implementation would no longer be appropriate, or the data quality controls and attention checks might be inadequate. If there are differences in time, place, or subject population between the two studies, corresponding changes to the materials, instructions, or procedure could be needed to provide an adaptation of the experimental paradigm to a new context. Such adaptation creates yet more challenges in interpretation: too many changes could cause differing results, but so could not enough changes. In sum, when replications fail, we generally do not know why they failed, although we may speculate.

For the goals of large-scale replication projects, it doesn’t matter why any particular study failed to replicate, because the aim is to estimate the proportion of replication effects in a literature. In contrast, however, when individual scientists attempt to replicate an effect with the goal of building on it, they do care about why an individual replication failed. In an uncertain literature, scientists might not want to commit resources to studying extensions of an effect without first checking that they can measure that effect themselves. For those individual scientists, it is much more important whether the replication failure is due to a fixable issue with the the replication or an intrinsic feature of the original result.

Re-replication can serve as a way to test explanations for replication failure. While it’s possible to speculate after the fact about potential causes of a single replication failure, in most circumstances these causes are hard to discern (absent clear evidence of errors). In contrast, a second replication provides a chance to test explanations by making modifications – as well as giving another chance for researchers to measure an effect of interest. But what are the chances that a re-replication succeeds?

Relatively few studies have estimated re-replication success. One estimate comes from Ebersole et al. (2020). After the original RP:P result of a replication rate around 40% (Open Science Consortium, 2015), Gilbert et al. (2016) raised concerns that methodological differences might explain low replication rate. In 11 of the RP:P studies, the original authors had raised concerns about protocol fidelity prior to data-collection. Of these 11 with concerns, 10 failed to obtain significant results in the RP:P replication. Thus, Ebersole et al. (2020) re-replicated 10 of these 11 in larger samples, using both the RP:P protocol and a new protocol revised under advice of the original authors or other experts. This study thus tested whether larger sample sizes and/or “better” methodologies would “rescue” the failed RP:P replications. The result was that 2 of the 10 revised protocols found a significant result (but not the 1/11 that originally was successful). Even when a significant effect was recovered, the effect size was much diminished (Ebersole et al., 2020). The re-replication success rate was thus 2/9 (22%) for studies with non-significant first replications, under favorable, high-resource circumstances.

While Ebersole et al. (2020) looked at re-replication success rate in a high resource setting with access to large, multi-site samples and expert input, most early career scientists do not have those kinds of resources to devote to re-replication attempts. On the other hand, early career researchers may also be prone to a different distribution of causes of initial replication failure. Thus, it is an open question what the re-replication rate is for failed replications of early career researchers. Further, estimating this rate could inform researchers’ decisions on what to do next after failed replications.

Here, we investigate re-replication in the context of graduate student replication class projects. Students in a graduate methods class on experimental methods in psychology were given the option to “rescue” an experiment that a student in a prior year had previously failed to replicate as their class project (first

replications reported in [Boyce et al., 2023](#)). The focus of the class was best practices in experimental design; thus, students looked at both the original paper and the failed replication to examine potential issues in the replication that they could fix in their rescue project. In the present paper, we report the results of 17 re-replication rescue projects. We find that a minority of projects (5/17, 29%) successfully recovered the original effect.

2 Methods

PSYCH 251 is a graduate-level experimental methods class taught by MCF. In previous years, students have conducted replication projects [Hawkins et al. \(2015\)](#). In Fall 2023, students were offered the option to complete a “rescue” project where they re-replicated one of the unsuccessful replications from a previous year. Students could also opt to do a normal replication instead. If they opted for a rescue, they were given the option to participate in a collaborative meta-science project and earn authorship on the current paper based on 1) completing a rescue project, 2) reviewing another student’s rescue project for analytic errors, and 3) reviewing and approving the final manuscript. We report on the result of 17 rescue projects that opted to be part of the paper and completed data collection.

A spreadsheet of projects, individual project write-ups (both first replications and rescues), links to individual project data and analyses for rescue projects, and the analytic code for this paper are all available at <https://osf.io/cyk5w/>.

Our analysis plan was pre-registered after students had selected projects, but before final data collection on the projects. Each project was also individually pre-registered by the student conducting it. The overall analysis is pre-registered at <https://osf.io/5qz7v>, individual pre-registrations are linked from [TODO LINK](#). We note one deviation from our pre-registration here: we pre-registered visual comparisons between original, first replication, and rescue projects using prediction intervals. Prediction intervals depend on both the original effect size and variance and the variance of the comparison (replication or rescue) study ([Patil et al., 2016](#)). Thus we cannot show a single prediction interval for the original study, but would have to show a prediction interval between each pair of studies. We thought this analysis would not offer additional clarity and hence we did not perform it.

2.1 Sample

The experiments that were re-replicated were chosen from studies that failed to replicate in [Boyce et al. \(2023\)](#). We created an initial list of 49 rescue-eligible studies that 1) had received a subjective replication success score of 0, .25 or .5 (on a 0–1 scale) in [Boyce et al. \(2023\)](#), 2) had a Github repository available (github repositories were used in class starting in academic year 2015-2016), and 3) where the original experiment had 200 or fewer participants (to ensure we could afford to match or increase the sample size based on the class budget). We then contacted the replication project authors for permission to share their report and repository with a new student and include it as a supplement on a resulting paper. This left 27 options for the students to choose from. 20 students chose to do rescue projects, and 3 students did not finish their project or did not indicate interest in being part of this paper, leaving a final sample of 17 rescue projects.

2.2 Procedure

Students conducted their rescue projects over the course of the 10-week class. Once they had chosen a project we gave them access to the original replicators’ write-up and repository, which often included the data, experiment code, and analytic code. In many cases, students were also given the contact information of the original replicator (a few original replicators opted not to be contacted by students).

Students were required to think of reasons the first replication might not have worked, and address them if they could. A list of possible reasons and solutions [TODO LINK](#) was given to students. In general, we encouraged students to add manipulation checks as appropriate, and to adapt their materials to online studies, which may benefit from attention checks and/or shorter duration. For instance, the rescue of [Paxton et al. \(2012\)](#) switched from using the cognitive reflection task (CRT) which many online participants are over-familiar with for the newer CRT-2 which is less overused but attempts to measure the same construct ([Thomson & Oppenheimer, 2016](#)). The rescue of [Jara-Ettinger et al. \(2022\)](#) discovered that the replication had accidentally used an illustrated version of the stimuli rather than the photographic stimuli used in the original and used the photographic stimuli instead. [Tarampi et al. \(2016\)](#)

had participants do a timed navigation task where they wrote L or R to indicate which way to turn at each intersection on a paper map. The replication ported this experiment online and had participants click a drop down menu to select left or write for each turn. The rescue removed the unwieldy dropdown menus and opted to have participants press keys on the keyboard to indicate the direction of a turn, which seemed like a more natural interface. Once experimental designs and analytic plans were approved by class TAs (VB and BP), students pre-registered and ran their samples.

With one exception, samples were collected on Prolific (the rescue of [Yeshurun & Levy, 2003](#) ran in-person on the Stanford student subject pool). We tried to power studies adequately (with a target of 2.5x original following [Simonsohn, 2015](#)), but due to cost constraints, not all studies were powered at this level. The rescues had on average 1.48 times the original sample post-exclusion (median: 1.07, IQR: 0.94 - 2.4, minimum: 0.48, maximum: 2.96, see Table 3 for all sample sizes). Across the 16 Prolific studies, we spent \$5471, for an average of \$342 per project.

2.3 Coding of results

We followed Boyce et al. (2023) in the properties of the studies we measure and how we quantify replication success. Each project was rated on the basis of subjective replication success (on a 0–1 scale) by both MCF and one of VB and BP. We thought about replication in terms of general match in key study results (direction, magnitude, and significance), rather than focusing on any singular numeric result or significance cut-off. Interrater reliability was 0.9; disagreements were minor (at no point greater than .25) and were resolved through discussion.

As a complement to the subjective rating of overall success, we statistically compared one key measure of interest for each study, following Boyce et al. (2023). In order to statistically compare the key measures, we needed effect sizes reported in the same way for each original study, first replication, and rescue. When effects were not reported in consistent ways across original and replications, we recalculated effects from raw data when necessary to obtain comparable values.

We measure statistical consistency using p -original, the p -value on the null hypothesis that one study’s population effect comes from the same distribution of population effects as another study or studies ([Mathur & VanderWeele, 2020](#)). If we assume no heterogeneity between studies, then this is the same as asking how consistent one study’s estimate of the population-level effect is with another study’s estimate of the population-level effect. However, meta-analyses of closely related studies, such as those from different sites of multi-site replications, indicate that there is often heterogeneity between studies. p -original allows for such heterogeneity, as governed by a parameter τ . We cannot accurately estimate the level of heterogeneity for an effect meta-analytically as we have only a small number of replications per study. Instead, we impute a heterogeneity value of $\tau = .21$ SMD, which is the average level of heterogeneity found by Olsson-Collentine et al. (2020) in prior multi-site replications in psychology.

We recorded the same set of potential correlates that were used in Boyce et al. (2023) for original, first replication, and rescue (these were already rated for original and first replication). These potential correlates included the subfield of the study (cognitive, social, or other psychology), its publication year, experimental design features including whether it was a within- or between-subject design, whether each condition was instantiated with one vignette or multiple, how many items each participant saw, and whether there were open materials and open data.

For the original study and each replication, we recorded the number of participants post-exclusions. For studies where some extra conditions were dropped in some replications, we counted only the participants in the key conditions all replications had for comparability. For instance, if an original study compared between two critical conditions but also had a baseline control, we did not count the participants in the baseline condition if a replication did not include this condition. We also recorded whether each study was conducted online using crowd-sourced platform or not.

3 Results

3.1 Overall replication rate

Our primary question of interest was how many of the 17 rescue projects succeeded at replicating the results in the original study. Across the 17 rescue projects, 5 mostly or fully replicated the original results according to the subjective replication ratings. 12 had a rating of 0, 2 got a rating of .75, and 3 got a

rating of 1. Thus, a first pass answer to the question “how often can a failed replication be salvaged?” is 29% (bootstrapped 95% CI: 12% - 53%) of the time.

In the original replication sample from Boyce et al. (2023), 76 out of 176 replications (43%) mostly or fully replicated (i.e. received a subjective replication score of .75 or 1). Note that Boyce et al. (2023) report the average replication score as a percent success (49%), but given that we considered studies with a subjective score of .5 as eligible to be rescued, we recomputed the success rate where scores of 0, .25, and .5 are considered failures and .75 and 1 successes. If the re-replication rate in our sample is representative of the re-replication rate for the initially non-replicating studies, then the combined chance of mostly or fully replicating in a first replication or one follow-up replication is 60%.

3.2 Effect size comparison

Figure 1: Standardized effect sizes of original studies, first replications, rescues, and additional replications if available. Due to the large effect size of a couple studies, large effect studies are shown in a separate panel. In a few cases, the first replication’s key effect was non-zero in the same direction as the original; however, in these cases the larger pattern of results was not fully consistent between original and first replication.

As a complement to subjective replication ratings, we also statistically compared the effect sizes of the rescue, first replication, and original study on one preregistered key measure per study (again following Boyce et al., 2023). Though we did not conduct a systematic review of the literature to identify all possible replications, we also consider the effect sizes obtained in additional replications when we were aware of them (either from other class projects, or external replications in the literature),

We standardized all effect sizes into standardized mean difference (SMD) units. One potential issue with comparisons using SMD is that noisier measures will have smaller standardized effect sizes even if the effect on the original scale is the same. In general, the replication and rescue effect sizes were smaller than the original effect sizes, and in a few cases the effects were in the opposite direction (Figure 1).

Scientists’ intuitions about whether a replication is successful and whether an effect provides support for a hypothesis (including heuristic cutoffs like $p < .05$) do not always align with measures of statistical consistency (Patil et al., 2016). For instance, two studies may both find that condition 1 results in a significantly higher outcome measure than condition 2, but the effect magnitudes may be sufficiently different that they are statistically unlikely to have come from the same population. On the other hand, one study may find a statistically significant, but imprecisely estimated effect in a small sample, and

Table 1: P-original values between different sets of experiments. The primary analysis is between the original result and the meta-analytic aggregation of all replications. All p-originals assume an imputed heterogeneity value of $\tau=.21$.

Todd et al. 2016	0.062	0.124	0.058	0.778
Yeshurun & Levy 2003	0.614	0.017	0.943	0.474

second study may find a near-zero (null) effect, but the effect estimates from the two studies may be statistically compatible, despite one supporting a hypothesized difference and the other not.

As our primary comparison, we compare the effect size of the original study to the meta-analytic effect of the totality of the replications (first replication, rescue, and additional if found). The value of p -original represents how likely an effect size equal to or more extreme than the original effect size is to occur if it comes from a distribution of population effect sizes defined by the mean and standard error of the replications (combined meta-analytically) with a between-population standard deviation of $\tau = .21$ (imputed from [Olsson-Collentine et al., 2020](#)). That is, it p -original is a measure of the statistical consistency of the original result with the totality of the replications, assuming a given level of heterogeneity of effects between studies. Smaller p -original values indicate more inconsistency.

The median value of p -original between an original study and its replications was 0.15 [IQR: 0.05 - 0.29]. 24% of the p -original values were less than .05, indicating by conventional thresholds a rejection of the null hypothesis that the original comes from the same distribution of population effects as the replications. Individual p -original values for each study are shown in Table 1.

As secondary measures, we calculated the p -original values between a) the original and the rescue, b) the original and non-rescue replications, and c) the rescue and other replications. For a) the original versus the rescue, median value of p -original was 0.06 [IQR: 0.01 - 0.52], and 47% of the p -original values were less than .05. For b) the original versus all the non-rescue replications, median value of p -original was 0.14 [IQR: 0.01 - 0.38], and 35% of the p -original values were less than .05. For c) the rescue versus the other replications, median value of p -original was 0.31 [IQR: 0.14 - 0.78], and 24% of the p -original values were less than .05.

Overall, allowing for a heterogeneity level of $\tau=.21$ SMD, a number of original effects are not statistically consistent with rescues and replication effects. The pattern of inconsistency does not align with which studies were rated as having replicated. In all cases, the point estimate of the re-replication is smaller than, or in the opposite direction of, the original effect on the key measure of interest.

Table 2: Correlations between an individual predictor and the subjective replication score of the rescue project. The first set of predictors were pre-registered based on the correlates used in Boyce et al. (2023). The last three predictors were added post-hoc.

3.3 Correlates of rescue success

Are there signals in the features of original or replication studies that predict whether a re-replication will succeed? To address this question, we report correlations between the set of predictor variables used in Boyce et al. (2023) and the subjective replication scores of the rescues. We also added some (non-preregistered) predictors related to the sample size of the first replication, after seeing the successful re-replications of Ngo et al. (2019) and Krauss & Wang (2003), both of which had small replication samples and larger rescue samples.

All of the correlations are presented in Figure 2. The number of rescues is small, and many of these predictors are correlated, so we caution against over interpretation.

The strongest correlates of rescue success were open materials, a small sample size on the first replication, a small sample size on the first replication relative to the original sample size, and a large rescue sample size relative to the first replication. None of the pre-registered correlates meet the conventional significance threshold; the two correlates based on ratios that reflect a relatively smaller replication sample size are marginally significant.

Small replication samples relative to original and rescue could be due to both a) powering a replication according to a reported large effect size or b) difficulties with recruitment or high exclusion rates leading to a smaller than intended sample. Since relative sizes of the studies may play a role in replication success and how probative replications are, we show the sample sizes in Table 3.

An additional factor that influences the interpretation of a replication is how close the replication’s methods were to the original. In the rescue projects, we aimed to have methods be as close as was feasible or appropriate. However, rescue projects varied in how close the re-replications actually were, often due to limitations in the availability of original stimuli and original instructions, in addition to the use of primarily online subject pools. Table 3 shows the closeness of each first replication and rescue according to the classification scheme from LeBel et al. (2018).

Overall, we do not have a clear picture of why certain studies replicated in the rescue sample and others did not, other than a few cases where fixing sample size issues may have helped.

3.4 Case studies

Given the mix of successful and unsuccessful rescues, we discuss a few projects where we have speculations about why they turned out the way they did.

The rescue of Krauss & Wang (2003) was successful despite an unsuccessful replication. This study

Table 3: Comparison of sample size for original, replication, and rescue samples and measures of closeness for replication and rescue samples.

looked at the influence of a guided thinking on whether or not people gave correct justifications (drawn or written) for their answer on the Monty Hall problem. The original paper reported correct justification from 2/67 (3%) in the control condition and 13/34 (38%) in the guided thinking condition. The first replication struggled to recruit participants who were naive to the problem (an exclusion criterion), and many participants give very short text responses in the provided text box (only textual responses were allowed). The replication found 0/8 correct justifications in the control and 0/11 in the guided thinking condition. While we can't know for sure what caused the non-replication, there were clear problems observable from the small final sample and low-quality responses. The rescue targeted these issues by adding a pre-screening that ensured participants were not familiar with the Monty Hall problem, switched the name of the problem (to reduce googling for answers), and had participants upload drawings for their justifications. Collectively, we believe these changes brought the rescue closer to the intent of the original. The rescue had 1/40 (2%) correct justifications in the control group and 6/35 (17%) in the guided thinking group. This effect was significant, though smaller than the effect in the original.

Ngo et al. (2019) was a second successful rescue. The original study found a large effect; hence the first replication, powering for 80% power on the reported effect, recruited a small sample of 12 people. This small study failed to find the original effect. The rescue, powered using 2.5x the original sample (as recommended by Simonsohn, 2015), recovered a clear effect (albeit a much smaller one). There are reasons to think that some effect sizes in the literature may be inflated Camerer et al. (2018), and it is also possible that changes to experiments or switches to online could result in noisier samples and thus smaller effect sizes. Therefore, replications with smaller samples than the original (even if powered to the original effect size), may not be very diagnostic, and could potentially benefit from a re-replication.

Not all rescues of small replications succeeded, however. Payne et al. (2008) was a study of the effects of sleep on memory consolidation. They showed participants a number of images and then hours later (after either sleep or no sleep) measured their recall for parts of the images. The first replication struggled to recruit participants to complete a followup session after sleep and only reported a sample size of 23 (the original had 48). The rescue attempted to recruit a larger sample (target 88), but also experienced difficulties getting participants to complete the second part of the experiment 12 hours after the first, managing also only to recruit 23 people. The lesson here may be that sleep research is difficult to conduct online. However, an online replication by Denis et al. (2022) reports qualitatively similar (but quantitatively smaller) results to Payne et al. (2008) on related but not identical measures.

@child2018 studied reading times for passages of text with different emotional valences written from either

a third-person or second-person perspective. They found a significant interaction between perspective and valence: participants read positively-valenced passages faster than negatively-valenced passages, but only when they were written from a second-person perspective. The first replication used a similar sample size to the original study (40) and found an effect that trended in the same direction, but was substantially smaller. The rescuer identified several possible reasons for this failure, foremost among them that the replication was conducted online while the original was conducted in person. It is reasonable to expect online studies of reading time to be noisier than in-person studies because the environments participants completed the study in varied much more online. The rescue attempt was still online, but used a much larger sample size to account for noisier data. Still, the rescue found a non-significant effect that trended in the opposite direction from the original and first replication. Even though the first replication trended in the same direction and there was an identifiable reason for the smaller effect size, increasing sample size did not rescue the effect.

4 Discussion

Faced with a failed replication, should investigators devote more time to continued replications? There are limited data that inform this decision. To address this gap, we presented the results of 17 new replications that attempted to “rescue” previous failed replications by identifying and ameliorating possible causes of non-replication. 5 of these rescue projects (29%) mostly or fully replicated the original results.

In some cases, increasing sample size and fixing internal validity issues in the replication seems to have led to a successful rescue (although we can’t establish causality even in these cases). However, there were other cases where the first replications had issues with a small sample or deviations in the implementation, and the rescue addressed these issues but still failed to replicate the original results. We can’t predict what replication failures are likely to resolve given another, more thoughtful try, beyond the suggestion to review studies for best practices in experimental design and sampling (e.g., [Frank et al., 2024](#)).

The rescues all showed smaller effect sizes than their original studies, regardless of whether the pattern of effects replicated. A large minority of replications had effect sizes that were statistically inconsistent with the original effect, even accounting for expected levels of heterogeneity between studies. These diminished and inconsistent effects suggest that even if a re-replication “works”, it may be difficult to build upon as follow-up studies will need large samples to detect small effects.

The reported rescue projects are a small sample of replications, leading to highly uncertain estimates. They are also chosen non-randomly, as they have been selected for twice based on student interest – once for the original replication and again for the rescue. However, this selection bias is likely to correlate with how graduate students and other early career researchers choose what topics to work on and what studies to build on. Nevertheless, our estimate is still broadly consistent with that of ManyLabs 5 (29% vs. 22%, [Ebersole et al., 2020](#)).

In cases where re-replications failed, we do not believe any conclusions are licensed about the status of the original results. Students conducting rescue projects put substantial effort into trying to set up rescues that had a good chance of success, but projects were constrained by budget limitations, a short timeline, and the constraint that most data collection needed to occur online. These limitations are representative of the sort of resource limitations often faced by early-career researchers. That said, it is possible that different results might be obtained in better-resourced settings, by scientists with more expertise and more time.

We opened with a question about what an early-career psychology researcher should do given a failed replication: should they try again or give up and move on? In our sample, the odds of a re-replication working are low (consistent with [Ebersole et al., 2020](#)). Especially if there is not a clear, identifiable candidate for replication failure, it may be more efficient to select another result to build on.

Acknowledgements

We thank the students from previous years of PSYCH 251 who graciously agreed to let us re-replicate their projects and shared their work with us. We thank the other members of 251 teaching team and students for feedback on projects. Data collection was supported by funding from the Stanford Departments of Psychology and Philosophy, Graduate School of Education, and the Symbolic Systems program.

Author Contributions

VB and MCF contributed to conceptualization. BP contributed to project administration, VB contributed to formal analysis, and MCF contributed to supervision.

Authors other than VB, BP, and MCF each designed, conducted, analyzed, and wrote up one of the projects – these authors contributed to investigation, formal analysis, and visualization.

VB wrote the first draft, BP and MCF did editing, and all authors reviewed the final manuscript.
